## Assessment Report

# FOR <br> Gulf of Maine Northern Shrimp -- 2000 

Prepared<br>October 5, 2000<br>by the<br>Atlantic States Marine Fisheries Commission's<br>Northern Shrimp Technical Committee<br>Mike Armstrong, Chairman (Massachusetts)<br>Margaret Hunter, (Maine)<br>Josef Idoine, (NMFS NEFSC)<br>Clare McBane, (New Hampshire)<br>Dave McCarron, (Massachusetts)<br>Daniel Schick, (Maine)<br>Amy Schick (ASMFC)

## INTRODUCTION

The Gulf of Maine fishery for northern shrimp (Pandalus borealis) is managed through interstate agreement between the states of Maine, New Hampshire and Massachusetts. The management framework evolved between 1972-1979 under the auspices of the State/Federal Fisheries Management Program. In 1980, this program was restructured as the Interstate Fisheries Management Program (ISFMP) of the Atlantic States Marine Fisheries Commission (ASMFC). The Fishery Management Plan for Northern Shrimp was approved under the ISFMP in October 1986 (FMR No. 9., ASMFC) and northern shrimp continues to be managed under this plan today. Amendment \#1 is currently under development to consider expanding the tools available to manage the fishery, anticipated for completion in the summer of 2001. Within the ISFMP structure, the Northern Shrimp Technical Committee (NSTC) provides annual stock assessments and related information to the ASMFC Northern Shrimp Section. Annually, the Section decides on management regimes after thorough consideration of the NSTC stock assessment, the input
from an industry advisory panel and comment from others within the shrimp fishing industry. Management under the 1986 FMP has been conducted primarily by seasonal closures and mesh size restrictions.

Stock assessments conducted in the 1980's and 1990's have keyed on strong year classes, (i.e. those hatched in 1982, 1987 and 1992). Each strong year class supports the shrimp fishery for about three years commencing about three years after hatching. The fishery was supported during the late 1980s and early and mid 1990s by the strong 1982, 1987 and 1992 year classes with other years depending on less robust year classes. The 1993 year class proved to be strong also, producing the first back-to-back strong year classes since the late 1960's. Based on the abundance of the 1992 and 1993 year classes, the NSTC recommended a full season for 19951996, but recommended reductions in fishing effort for December, April and May for the 199697 fishery to afford some protection for small shrimp in the offshore areas. The NSTC recommended limiting the fishery to February and March for the 1997-98 season and a 40-day season during the months of February and March in 1998-99 to protect the berried females and young shrimp in light of a rapidly declining resource. The NSTC recommended two options for the 1999-2000 fishing season: 1) closed season; 2) open February 14-March 18 or February 16March 14 and May 7-31.

The Northern Shrimp Section, at its 1999 fall meeting, approved a 51 day season that began January 17, 2000 and ended March 15, 2000. This is the third year days available to the fishery has been reduced in recent years, with prior years showing a steady increase ( 90 opportunity days in 1999, 105 days in 1998 versus 156 days in 1997, 152 days in 1996, 128 days in 1995, and 122 days in 1994). In addition, the Section continued to require the use of a finfish excluder device known as the "Nordmore Grate" throughout the shrimp fishing season.

The following report presents the results of the Technical Committee's 2000 stock assessment. Analyses and recommendations are based on: 1) research vessel survey data collected by the Committee during summer and by Northeast Fisheries Science Center (NEFSC) during spring and autumn, 2) commercial landings data collected by the National Marine Fisheries Service
(NMFS) port agents, 3) biological sampling of the commercial landings by personnel from the participating states and the NMFS, and 4) data from vessel trip reports filed by shrimp fishers. In addition to previously used traditional methods of assessing the stock (i.e. landings data, commercial effort and CPUE estimates, indices of abundance, etc.) more innovative, quantitative tools, the DeLury, ASPIC surplus production, yield per recruit and eggs per recruit models were introduced in 1997 and continue to be used to provide guidance for management of the stock.

## Commercial Fishery Trends

## Landings

Annual landings of Gulf of Maine northern shrimp declined from an average of 11,400 metric tons (t) during 1969-1972 to about 400 t in 1977, culminating in a closure of the fishery in 1978 (Table 1). The fishery reopened in 1979 and landings increased steadily to over 5,000 t by 1987. Landings ranged from 2,300-4,400 t between 1988-1994. The 1995 season showed a dramatic rise to $6,500 \mathrm{t}$. The 1996 season saw a further rise in landings to $9,200 \mathrm{t}$, the highest since 1973 . In 1997 the landings declined to 7,200, and the decline continued in 1998 to 4,174 t and in 1999 to $1,816 \mathrm{t}$. Landings increased slightly to $2,390 \mathrm{t}$ in 2000 . The 2000 season of 51 allowable fishing days was the shortest in recent history (Table 2).

Maine landed $87 \%(2,067 \mathrm{t})$ of the 2000 season total while New Hampshire and Massachusetts landed $9 \%$ (212 t) and 5\% (110 t), respectively. This proportional distribution of landings by state has been generally consistent over the past several years. (Table 1, Figure 1). Like past years, in 2000 the months of January and February yielded the highest percentages of the catch, while March exhibited the lowest (Table 2).

## Size Composition of Landings

Size composition data (Figure 4), collected since the early 1980's, indicate that trends in landings have been determined primarily by recruitment of strong (dominant) year classes. Landings more than tripled with recruitment of a strong 1982 year class in 1985 and 1986. The 1987 season landings of $5,300 \mathrm{t}$ (Table 1) were supported in large part by mature females (assumed age 5)
from this year class. Landings declined sharply in 1988 with the passage of this year class through the fishery. A strong 1987 year class began to recruit to the fishery in spring of 1989 and was a major contributor to the 1990-1992 fisheries (NSTC Assessment Reports, 1988-1993). The 1992 year class was the first year class of notable size since 1987 and began recruiting to the fishery in March and April 1995. The 1992 year class was supplemented by a moderate sized 1993 year class, which partially supported the relatively large annual landings in 1995, 1996 and 1997. The early months of the 1998 season showed high catches from the last of the 1993 year class coming ashore as second year females. The 1999 season showed low landings due to very poor recruitment in 1994 and 1995, and only average recruitment in 1996.

Length frequencies obtained from dockside sampling in Maine (Figure 2), New Hampshire and Massachusetts (Figure 3) during the 2000 season showed that the sampled catch consisted primarily of (assumed) age 3+ females having a mid-dorsal carapace length of 22.5 mm and greater, reflecting a capture of the 1996 year class. Relatively low catches of males and immature females were landed throughout the season from the 1998 and 1997 year classes respectively. The large proportion of females landed translated into the same number of shrimp caught during the 2000 season as in the 1999 season, with a higher weight of total landings. The late start to the season protected some females through egg drop in January. By February, most females had dropped their eggs in Massachusetts, while the majority of females in Maine dropped them by March.

## Effort and Distribution of Effort

Effort in the northern shrimp fishery (measured by numbers of trips in which shrimp gear is used) has increased considerably since the late 1970's. Most fishing is conducted by otter trawls, although traps are also employed off the central Maine coast. Maine trapping operations accounted for between $4 \%$ to $8 \%$ of the state's total number of trips from 1987 to 1994 . The total number of trawl trips in the fishery peaked at 12,300 during the 1987 season (Table 3, Figure 5). Increases in season length, shrimp abundance and record ex-vessel prices coupled with reduced abundance of groundfish all contributed to this increase. Effort subsequently fell to an average of 9,500 trips for the 1988,1989 , and 1990 seasons, fell further to an average of 7,900 trips in the

1991 and 1992 seasons, and declined to 6,000 trips in the 1994 season. Effort nearly doubled between 1994 and 1996 and then declined again from the 1996 level of 11,791 to 3,811 in 1999, and 3,382 in 2000 (Table 3). While approximately 310 vessels participated in the shrimp fishery in 1997 and 260 vessels in 1998, there were about 238 participants in the 1999 fishery and many of these only fished for a few days. The majority (181) were from Maine, while the number of vessels from New Hampshire ports remained at about 30, and the numbers from Massachusetts declined from the 33 vessels in 1998 to 27 in 1999. Vessel information for the 2000 season has not been analyzed yet.

Prior to 1994, effort (numbers of trips by state and month) was estimated from landings data collected from dealers and landings per trip information from dockside interviews of vessel captains. In the spring of 1994, a logbook reporting system replaced the collection of effort information from interviews. Since 1995, landings per trip (LPUE) from vessel trip reports have been expanded to total landings from the dealer weighouts:

The vessel logbook database is currently incomplete and has not been thoroughly audited (for an evaluation of vessel trip report data see NEFSC 1996). Therefore, effort estimates reported here for recent years should be considered extremely preliminary. Logbooks (VTR's) were required of every shrimp fisherman for the first time in the 2000 fishery. Thus measuring the distribution of effort will become much more accurate in the future.

The 1996 assessment report (Schick et al. 1996) provides a comparison of 1995 shrimp catch and effort data from both the NEFSC interview and logbook systems and addresses the differences between the systems.

Seasonal trends in distribution of effort have been evaluated over the past 8 years. The relative magnitude of offshore fishing effort has varied in earlier years (1990-1993), reflecting seasonal movements of mature females (inshore in early winter and offshore following larval hatching),
but also reflect fishermen's choices for fishing on concentrations of shrimp. The 1994 fishery stayed in deep water only through the beginning of January, shifted inshore through the middle of March and then moved into deeper water for the duration of the season. The 1995 fishing patterns revealed an early inshore migration in December and an early offshore migration with most fishing occurring offshore even during March. The 1997 fishing season saw offshore fishing continue throughout the year with $44 \%$ of the sampled trips in January and February coming from 55 F or deeper and almost all the trips from the other months coming from offshore. The 1996 and 1998 season's fishing pattern mirrored that of 1994. The 1999 season's effort was all offshore in December and almost all offshore in January. Effort moved inshore in February and remained primarily inshore throughout March. Effort in April and May was all offshore. This distribution of effort reflects the fact that the main body of shrimp available to the fleet was from the 1996 year class and they were split between transitionals that remained offshore and early maturing females that made some shoreward migration during the winter. During the 2000 season effort was almost entirely inshore in January and February and increasingly offshore in March.

## Catch per Unit Effort

Catch per unit effort (CPUE) indices have been developed from NMFS interview data (19831994) and logbook data (1995-2000) and are measures of resource abundance and availability (Figure 5). Pounds landed per trip increased from 735 pounds in 1983 to over 1,300 pounds in 1985 when the strong 1982 year class entered the fishery. CPUE subsequently dropped to below 750 pounds/trip in 1988 but increased to 1,050 pounds in 1990 with entry of the strong 1987 year class. This index averaged 980 pounds between 1991-1992, declined to 767 pounds in 1993, and increased in 1994 to 1,074 pounds. The 1995, 1996 and 1997 CPUEs, from logbooks, rose sharply to 1,362 pounds in 1995 , rose again to 1,713 in 1996 and declined to 1,455 in 1997. The CPUEs for 1996 and 1997 were the highest since the early 1970's. The 1998 CPUE was 1,317, showing a continued high level compared to earlier years and the 1999 CPUE dropped to 1,067 pounds per trip, which is still considerably higher than in previous years with poor recruitment. The 2000 CPUE increased to 1,557 pounds per trip. A trip may be a misleading unit of effort,
because estimates from both interviews and logbooks include multiple day trips in the spring and there may be an increasing number of such trips in recent years.

More precise CPUE indices (pounds landed per hour fished), have also been developed for both inshore ( $<55 \mathrm{~F}$ ) and offshore ( $>55 \mathrm{~F}$ ) areas using information collected by Maine's and New Hampshire's port sampling programs. The inshore CPUE in 2000 increased to 288 pounds per hour towing compared to CPUEs of 158 in 1998 and 1999 after dropping from a high of 304 in 1996 and 206 in 1997. The offshore CPUE dropped steadily from 203 pounds in 1996 to 192 pounds in 1997, 151 pounds in 1998 and 146 pounds in 1999, then jumped to 337 pounds in 2000. The total CPUE in 2000 was 292, nearly double the 1998 and 1999 values of 154 and 152 respectively. This value was the highest on record, exceeding the 1996 value of 251 , and equivalent to or exceeding peak years during previous periods when there were strong year classes in the fishery.

The CPUE from the port sampling interviews agrees well with the catch per trip data from logbooks (see text table below). While occasional trips with CPUE in excess of 300 pounds were recorded in 1994 and were considered to be high catch rates, several trips with CPUE in excess of 600 pounds per hour towing were recorded in 1995 and several trips in excess of 700 pounds per hour fished were recorded in 1996. One harvester reported a CPUE of over 1000 lbs./hr for one of his fishing days. In 1997, the sampled catch exceeded 600 pounds per hour once, showed 10 trips over 400 and 22 trips over 300. The five highest catch rates in the 1998 sampled catch were $485,408,349,346$ and 345 pounds per hour towing while in 1999 the CPUE exceeded 300 pounds per hour towing only once. The port sampling interviews for Maine for January 2000 gave 1 trip with a CPUE of over $1000 \mathrm{lbs} . / \mathrm{hr}$, 5 more that exceeded 700, and 7 more over $400 \mathrm{lbs} . / \mathrm{hr}$, out of 23 total interviews. The CPUE declined in February, with no trips over 700, and 3 trips over 400, out of 31 total. The 3 interviews made in Maine in March all had a CPUE of about $100 \mathrm{lbs} . / \mathrm{hr}$.

## ME/NH CPUE in lbs./hour towed, from port sampling. Catch (lbs.)/trip is from NMFS weighout and logbook data.

| Year | Inshore $(<55 \mathrm{~F})$ | Offshore $(>55 \mathrm{~F})$ | Total | Catch/trip |
| :--- | :--- | :--- | :--- | :--- |
| 1991 | 94 | 152 | 140 | 988 |
| 1992 | 132 | 93 | 117 | 974 |
| 1993 | 82 | 129 | 92 | 767 |
| 1994 | 139 | 149 | 141 | 1,074 |
| 1995 | 172 | 205 | 193 | 1,362 |
| 1996 | 340 | 203 | 251 | 1,713 |
| 1997 | 206 | 192 | 194 | 1,455 |
| 1998 | 158 | 151 | 154 | 1,317 |
| 1999 | 159 | 146 | 152 | 1,067 |
| 2000 | 288 | 337 | 292 | 1,557 |

## Resource Conditions

Trends in abundance have been monitored since the late 1960's from data collected in Northeast Fisheries Science Center (NEFSC) spring and autumn bottom trawl surveys and in summer surveys by the State of Maine (discontinued in 1983). The state-federal shrimp survey was initiated by the NSTC in 1984. The latter survey is conducted each summer aboard R/V GLORIA MICHELLE employing a stratified random sampling design and gear specifically designed for Gulf of Maine conditions. Strata sampled, and catch per tow data for the 2000 summer survey cruise are plotted in Figure 6. The NSTC has placed primary dependence on the summer survey for fishery-independent data used in stock assessments, although NEFSC spring and autumn survey data have been valuable as well.

There has generally been good agreement between the NEFSC autumn survey index (stratified mean catch per tow, kg ) and fishery trends (Figure 7). The index declined precipitously as the fishery collapsed during the 1970s; this was followed by a substantial increase, with peaks in 1986, 1990 and 1994, reflecting recruitment and growth of the strong 1982, 1987 and 1992 year classes and the above average 1993 year class. After declining to 1.1 kg per tow in 1996 with passage of the 1992 year class through the fishery, the index rose sharply in 1998, reflecting recruitment of the 1996 year class at age 2 (trends for the NEFSC spring survey index are similar). This year class was reported to be of above average size in the 1997 and 1998
assessments. This year class predominated in NEFSC 1998 autumn survey catches, with catches from other year classes being minor. The 1999 NEFSC fall survey index remained high, indicating remaining strength in the 1996 year class.

Abundance and biomass indices (stratified mean catch per tow in numbers and weight) for the state-federal survey from 1984-2000 are given in Table 4, length-frequencies by cruise are provided in Figure 9. Table 4 provides indices for all size/age groups, indices for age 1.5 animals and indices for shrimp $>22 \mathrm{~mm}$ mid-dorsal carapace length. The catch per tow in numbers of 1.5-year old shrimp (the total number in the first size modes in Figure 9) represents a recruitment index which, although the shrimp are not fully recruited to the survey gear, appears sufficient as a preliminary estimate of year-class strength. Individuals $>22 \mathrm{~mm}$ will be fully recruited to the upcoming winter fishery (primarily age 3 and older) and thus survey catches of shrimp in this size category provide indices of harvestable numbers and biomass for the coming season.

Again, all of these indices have shown peaks which reflect recruitment of the strong 1982, 1987 and 1992 year-classes (Table 4, Figure 8). The 1992 year class observed at (assumed) age 1 in the 1993 summer survey (Figure 9) was smaller than the dominant 1982 and 1987 year classes, but was followed by the above-average 1993 year class. These two year classes supported the fishery in 1996-1997. The 1996 year class appears comparable to the 1993 year class (Table 4, Figure 9) with this exception, recruitment since 1993 has been poor, with the 1997 and 1998 year classes being among the weakest in the time series (Figure 9). Thus, up through 1999 the only significant source of potential recruitment to the future winter fisheries was that provided by the 1996 year class. The 1996 year class dominated landings throughout much of the 1999 fishing year. The 1999 year class, seen for the first time in the summer 2000 survey, is comparable to the 1996 year class and thus is larger than recent year classes. The 2001 fishing year will be predominantly on the remainder of the 1997 year class and on the relatively weak 1996 year class. The larger 1999 year class will barely be within the selectivity of the fishing gear and so only a small proportion of this class will be caught in 2001.

Since 1995, there has been a consistent downward trend in the total number and biomass indices, with 1999 values being at or near the lowest observed. The 2000 index of harvestable biomass increased to 3.2 kg per tow from 1.9 kg per tow on the transformed scale. This increase likely reflects the reduced exploitation in the last two fishing years. The index is still well below historical levels. The total number per tow doubled from 398 in 1999 to 807 in 2000, reflecting primarily the recruitment from the 1999 year class. While we are encouraged by the 1999 year class strength, we feel resource conditions remain poor for the 2001 fishing year as all indices are well below historical levels.

## ANALYTICALSTOCK ASSESSMENT

Descriptive information for the Gulf of Maine shrimp fishery (total catch, port sampling, trawl selectivity, survey catches, and life history studies) were modeled to estimate fishing mortality, stock abundance, and candidate target fishing levels. The analytical stock assessment comprises three fishery models: modified DeLury analysis tracks the removals of shrimp using summer survey indices of recruits and fully-recruited shrimp scaled to total catch in numbers (from dealers' reported landings and port sampling); surplus production analysis models the biomass dynamics of the stock with a longer time series of total landings and three survey indices of stock biomass; a yield-per-recruit and eggs-per-recruit model simulates the life history of shrimp (including growth rates, transition rates, natural mortality, and fecundity) and fishing mortality on recruited shrimp using estimates of trawl selectivity to estimate yield and egg production at various levels of fishing mortality for guidance on what levels of fishing are most productive and sustainable.

DeLury results are summarized in Table 5 and Figures 10 and 11. Abundance and catchability were relatively well-estimated, and the model fit the data well. Estimates of recruitment to the fishery averaged 0.8 billion individuals, peaked at 1.3 billion before the 1990 fishing season, but decreased to 0.4 billion at the end of the 1999 season, the lowest level in the time series. Recruitment in 2000 increased to 0.6 billion but remained below the time series average. Fullyrecruited abundance averaged 1.0 billion individuals and peaked at 1.5 billion before the 1991
season. Fully-recruited abundance decreased to a time series low of 0.4 billion in 1999 and increased slightly to 0.5 billion in the current year. Total stock biomass estimates averaged about $14,000 \mathrm{mt}$, with peaks at over $22,000 \mathrm{mt}$ before the 1985,1986 , and 1991 seasons, and a decrease to a time series low of 5,700 mt in 1998. Total stock biomass has increased slightly over the last two years to its current value of $7,400 \mathrm{mt}$ (Figures 10, 11).

Annual estimates of fishing mortality averaged 0.34 ( $26 \%$ exploitation) for the 1985 to 1995 fishing seasons, peaked at 0.85 ( $52 \%$ exploitation) in the 1997 season and decreased to 0.23 ( $18 \%$ exploitation) in the 2000 season (Table 5; Figures 10, 11). The recent pattern in F reflects the pattern in nominal fishing effort (Figure 5). Precision of DeLury estimates was assessed by "bootstrap" analysis, in which survey measurement errors were randomly shuffled 200 times to provide simulated replications of the model. Bootstrap results suggest that estimates of abundance, biomass and mortality were relatively precise. A retrospective analysis showed that the model overestimated F and underestimated biomass in 1999.

An alternative method of estimating stock size and F was used to corroborate results from DeLury analysis. A surplus production model was fit to seasonal catch and survey biomass indices from 1968 to 1999 (summarized in Table 6). Estimates of F from the biomass dynamics model generally confirm the pattern of estimates from the DeLury model; F in $2000(\mathrm{~F}=0.21)$ has decreased from a peak of 0.55 in 1997 but is up slightly from 1999. The starting biomass in 1999 (9,861 mt) was the lowest since 1980 (Figures 12 and 13) and has increased to $10,090 \mathrm{mt}$ in 2000.

Yield per recruit and percent maximum spawning potential were estimated for the Gulf of Maine northern shrimp fishery (Figure 14). Yield per recruit was maximum at $\mathrm{F}=0.77$ ( $\mathrm{F}_{\text {max }}$ ) ( $48 \%$ exploitation) (Table 7). The increase in yield per unit F decreased to one tenth the initial increase at $\mathrm{F}=0.46\left(\mathrm{~F}_{0.1}\right)$ ( $33 \%$ exploitation). Maximum spawning potential (i.e., with no F ) was 2,395 eggs per recruit. Spawning potential was reduced by half at $\mathrm{F}=0.25$ ( $\mathrm{F}_{50 \%}$, 20\% exploitation).

As concluded by the Stock Assessment Review Committee, the stock was not replacing itself when spawning potential was reduced to less than $20 \%$ of maximum, and the stock collapsed when egg production was reduced further. Reproductive success for Gulf of Maine northern shrimp is a function of population fecundity and spring seawater temperature (Figure 14). Therefore, $\mathrm{F}_{20 \%}$ may be an appropriate overfishing threshold, which would result in target Fs well below 0.6. A sustainable target F may be the average F from 1985 to 1995 , which was 0.34 (which allows 40\% egg production per recruit).

## SUMMARY AND CONCLUSIONS

The back-to-back strong 1992 year class and moderately strong 1993 year class produced the bulge in the catch in the northern shrimp fishery between 1994 and 1998. This has not occurred since the late 1960's. These strong year classes have now passed out of the fishery.

Landings in 2000, 2389 t , were up from 1999, 1816 t , but were still down considerably from the 1998 landings and reflect a high initial CPUE and a season of only 51 days. While it was felt that the low landings in 1999 were caused by several environmental, biological and market factors and thus might not have been a clear indicator of the condition of the stock, likewise, the 2000 landings are believed to be the result of several factors. While commercial CPUE in 1999 continued a steady decline from the 1996 level of $1713 \mathrm{lbs} . /$ trip to $1067 \mathrm{lbs} . / t r i p$, commercial CPUE in 2000, 1557 lbs./trip, was the second highest in the time series behind 1996. The number of trips in 2000, 3382, was lower than in 1999, 3811, was dramatically lower than the high in 1996 of 11,791, and reflected the short season.

Short-term commercial prospects are reasonably favorable even though abundance remains relatively low. The improved prospect for the coming season is due to the average sized 1996 year class being second year females this year and the low landings in 1999 having left a good share of them in the water.

Indices of the status of the stock are taken from the commercial fishery, i.e. catch and CPUE and from fishery independent resource surveys, i.e. NEFSC spring and fall bottom trawl surveys, state-federal summer shrimp survey. The catch in 2000 was the third lowest since 1983 and reflects primarily the short fishing season of 51 days. The fishery's CPUE of 1557 pounds per trip from logbook and weighout data is the second highest in the series since 1991. The ME-NH season average CPUE of 292 pounds per hour towing from port sampling interview data is the highest in the data series from 1991. This value is high primarily due to the very high CPUE's in January. These may have been caused by the delayed start of the fishery, the predominance of the shrimp biomass being in the 1996 year class and a possible push ashore from warm bottom water offshore.

The NEFSC spring survey showed an increase in catch per tow in 1998, but a decrease to a relatively low number in 1999. The NEFSC fall survey index increased in 1998 and remained high in 1999. Both surveys tend to show a one-year-duration spike in catch per tow for stronger year classes of shrimp around age two or three. With the passage of the 1996 year class through that age group, the increases in 1998 in these two survey indices are normal. The fact that the fall index remained high in 1999 is not normal and indicates that the 1996 year class may be stronger than estimated. The state-federal summer shrimp survey in 2000 showed improvement over the record lows in 1999 and was punctuated by the appearance of a moderately strong 1999 year class at age 1.5. The abundance index was up to 807 shrimp/tow from 398 in 1999, the biomass index was up to $6.4 \mathrm{~kg} /$ tow from 5.8 in 1999, the recruitment index (age 1.5) was up to 382 shrimp/tow from 100 in 1999 and the harvestable biomass index was up to $3.2 \mathrm{~kg} /$ tow from 1.9 in 1999. While these indices are still not very good, they represent a turnaround in the steady decline seen since 1996.

Analytical methods mirror the results of the individual survey indices and catch records, in that the DeLury model shows an F of 0.23 , down from 0.50 for 1999 and this low F level may allow a rebuilding of the stock. The model also shows a higher biomass, 7397 t in 2001 and gives a higher biomass for $1999,6004 \mathrm{t}$, than it did in last year's run, 5019 t . The surplus production model shows a fairly low F and an improving biomass in 2001. The model is suitable for
indicating long term trends, but values of F and B from individual years should not be used as accurate estimates. Yield per recruit analysis shows an Fmax of 0.77 and an F0.1 of 0.46. The F of 0.23 for the 2000 fishery is much lower than F0.1, a commonly accepted upper limit for F (Table 7). The eggs per recruit model shows the 1999 F to be very close to F50\%, considered to be a level conducive to rebuilding the stock. The committee feels that F should be kept near 0.25 (F50\%), an admittedly arbitrary rebuilding level of harvest. A fishing mortality of 0.34 , which is equal to $\mathrm{F} 40 \%$ and the 11 year mean recommended by the SARC review for sustainable harvest, is not as likely to allow the stock to recover from its current low level.

## RECOMMENDATION

The Northern Shrimp Technical Committee bases its recommendation to the Section on the biology of the species and the opportunity for improving resource conditions in the future.

The Committee is encouraged that the sharp reduction in landings over the last two seasons has resulted in a relatively low F and a stabilization of the population abundance. Owing to the small population increase that has occurred, the Committee recommends that the Section allow a modest increase in landings during the 2000-2001 fishing season as compared to last year's landings. This will allow F to remain low and provide increased probability of stock rebuilding. The stock remains at a low level ( $7,400 \mathrm{mt}$ ) relative to the biomass present during the 1980's and early 1990's (average 1985-1995 biomass $=16,600 \mathrm{mt}$ ) and recruitment continues to be below the time series average.

Exploitable biomass has increased about $21 \%$ since last season. Thus, if F were calculated on biomass, landings of $21 \%$ greater would maintain F at the rebuilding target of about 0.25 for the 2000-2001 fishing season. However, because the average size of shrimp landed this season is likely to be smaller (recent (1995-2000) average size of $10.56 \mathrm{~g} /$ individual versus lasts year's average of $11.41 \mathrm{~g} /$ individual), landings must be adjusted by this amount (about $7 \%$ ) since F is calculated based on number of individuals removed from the population rather than weight. An increase in landings of $14 \%$ may result in an F about the same as last year (0.23). The Technical

Committee recommends that the resulting figure, 2850 mt , be the upper limit for landings in the 2000-2001 fishing year.

The Technical Committee recommends a 61-day season for the upcoming fishing year. This is a $20 \%$ increase from last season and will likely result in a modest increase in landings. From a biological viewpoint, the 2000 season provided increased benefit to the stock by controlling landings, providing the opportunity for egg drop by some individuals and by minimizing the catch of smaller individuals. The Committee encourages the Section to use this season as a base for formulating the upcoming season.

The Committee has no recommendation concerning the placement of the additional ten days, recognizing that applying all days at the beginning of the season will impact larval production and applying days at the end of the fishery may cause the harvest of smaller shrimp resulting in a higher F and an impact on future yield.

The Technical Committee notes the uncertainty in the estimates of F and stock abundance associated with the terminal years of the DeLury model. There is also considerable uncertainty in projecting the exploitable biomass at the time of the summer survey to the fishing season and in predicting the size distribution of the catch in the upcoming season. The Committee urges caution in setting management options as estimates of both F and stock abundance are subject to change in both directions, i.e., these parameters may be over- or underestimated in any given year. In addition, while the 1999 year class appears strong, the 1997 and 1998 year classes remain below average. These weaker year classes will enter the fishery over the next two seasons and therefore stock rebuilding may slow or cease if landings are allowed to rise sharply.

## ACKNOWLEDGMENTS

The Committee sincerely thanks all those people that have contributed to this assessment through their time and efforts as part of the scientific crew on the R/V Gloria Michelle shrimp survey, as port samplers, sample processors and data entry personnel. Working under conditions that are less than ideal, they have collectively made this effort possible.
